Abstract

A trinucleotide circular code is a set of trinucleotides allowing the reading frame in genes to be retrieved locally, i.e. anywhere in genes and in particular without start codon, and automatically with a window of a few nucleotides. In 1996, a common circular code X has been identified simultaneously in two large populations of eukaryotic and prokaryotic genes. The method proposed here identifies periodic signals of this code X in the two frameshift types (+1 and –1) of both eukaryotic and prokaryotic frameshift genes. As expected by the code theory, the circular code modulo 3 signals move in the same direction of translational frameshifting. Finally, in 68% of frameshift genes in the RECODE 2 database, the frameshift type (+1 and –1) is automatically identified using only this circular code periodic signal. This circular code information constitutes a new structural property of frameshift genes. It may be used directly or in association with existing methods to identify frameshift genes in genomes and their encoded proteins.

Introduction

In 1996, a trinucleotide circular code has been identified simultaneously in eukaryotic and prokaryotic genes [1,2]. It allows their reading frame to be retrieved. Frameshift genes, by bypassing or rereading one nucleotide, shift translation. Therefore, a theoretical forecast of circular codes should lead to a shift in this class of genes. This hypothesis is verified in this paper. Frameshifting and circular code are briefly presented.

Frameshifting

By our convention, the reading frame in a gene established by a start codon ATG, GTG or TTG is the frame 0, and the shifted frames 1 and 2 are the reading frame 0 shifted by one and two nucleotides in the 5′ – 3′ direction, respectively.

In the reading frame of a gene, a series of three nucleotides (codons) is translated into a series of amino acids according to the genetic code. The correspondence between the nucleotide sequence and the protein sequence is determined by genetic codes that are well-conserved across species.

However, in some cases, the protein synthesized by the ribosome does not correspond to the transcribed mRNA because of a translational error [3]. These translational errors are not the consequence of a genetic code alteration but they result mainly in a change in the ribosome translation site on the mRNA. This site modification could be expressed in different ways as a frameshifting, a stop codon reading through or a ribosomal hopping [4,5,6].

There exist two types of triggers that can stimulate the translational errors: instant and programmed. Instant translational errors are very rare with a rate estimated to 3 × 10⁻¹ [7]. Programmed translational errors are produced by different means including a special motif, a secondary structure in the mRNA or a cell lack of an amino acid. These events can increase the probability of a translational error up to near 100% [4].

Frameshifting is a translational error where the ribosome pauses the translation then bypasses one nucleotide and hence shifts translation of the reading frame from frame 0 to frame 1 (+1 frameshift) (Figure 1) or it rereads one nucleotide and hence shifts translation of the reading frame from frame 0 to frame 2 (–1 frameshift) (Figure 2). Then, the ribosome continues to translate the codons in the shifted frame until it encounters a stop codon in its frame. In some rare cases, the number of nucleotides bypassed or reread may vary. The protein product is then partially encoded by frame 0 and partially encoded by this shifted frame [8,9].

The frameshift prediction using computational methods is a difficult task due to the diversity of motifs and secondary or tertiary structures which stimulate frameshifting. Besides, these computational methods generate many frameshift gene candidates. However, alignment methods of frameshift genes determined experimentally constitute a classical approach to identify frameshifts [10,11,12]. For the –1 frameshift identification, some computational methods consider the primary and secondary structure of mRNA associated with the frameshift site. This structure is classically composed of a slippery heptamer X,XY,YYZ (X, Y and Z are three nucleotides and the comma “,” represents the frame 0) separated by five to nine nucleotides from a stem loop (Figure 3). The approaches based on this structural model also allowed several frameshift genes to be identified (e.g. [13,14,15,16]).

Common circular code

In 1996, two statistical studies, a codon frequency per frame and a codon correlation function per frame, showed that the 64 trinucleotides T = {AAA, . . . , TTT} are preferentially distributed in the three frames of genes [1,2]. By excluding the four trinucleotides with identical nucleotides T0 = {AAA, CCC, GGG, TTT} and by assigning each trinucleotide to a preferential frame (frame of its highest occurrence frequency), the same three subsets X0, X1, and X2 of 20 trinucleotides are found in the frames 0, 1, and 2, respectively, of two large and different gene populations (protein coding regions): eukaryotes (26,757 sequences, 11,397,678 trinucleotides) and prokaryotes (13,686 species).

sequences, 4,709,758 trinucleotides) (Table 1) [1,2]. These three trinucleotide subsets present several strong biomathematical properties, particularly the fact that they are circular codes.

We recall the definitions and the main properties of this common circular code which will be involved in this paper.

**Notation 1:** The letters (or nucleotides or bases) define the genetic alphabet $\mathbb{A}_4 = \{A,C,G,T\}$. The set of non-empty words (words respectively) over $\mathbb{A}_4$ is denoted by $\mathbb{A}_4^*$ ($\mathbb{A}_4^+$ respectively). Let $x_1, \ldots, x_n$ be the concatenation of the words $x_i$ for $i = 1, \ldots, n$.

**Definition 1:** Code: A set $Y$ of words is a code if for each $x_1, \ldots, x_n, y_1, \ldots, y_m \in Y$, $n, m \geq 1$, the condition $x_1 \ldots x_n = y_1 \ldots y_m$ implies $n = m$ and $x_i = y_i$ for $i = 1, \ldots, n$.

**Definition 2:** Circular code: A code $Y$ is circular if for each $x_1, \ldots, x_n, y_1, \ldots, y_m \in Y$, $n, m \geq 1$, the conditions $x_1 \ldots x_r = y_1 \ldots y_s$ and $x_1 = rs$ imply $n = m$, $r = e$ (empty word) and $x_i = y_i$ for $i = 1, \ldots, n$.

**Definition 3:** Trinucleotide circular code: A circular code of words over $\mathbb{T}$ is called a trinucleotide circular code.

In other words, a trinucleotide circular code $Y$ is a set of trinucleotides such that all sequences (e.g. genes) generated by concatenation of words of $Y$ and written on a circle, where the last letter is followed by the first one, have only one decomposition (factorization) into words of $Y$. If a sequence has two decompositions then $Y$ is not a circular code. As an example, let the set $Y$ be composed of the six following trinucleotides: $Y = \{AAT, ATG, CCT, CTA, GGC, GGC\}$ and the sequence $w$, be a series of the nine following letters: $w = ATGGCCCTA$. The sequence $w$, written on a circle, can be factorized into words of $Y$ according to two different ways: $ATG, GCC, CTA$ and $AAT, GCC, CCT$, the commas showing the way of decomposition (Figure 4). Therefore, $Y$ is not a circular code. In contrast, if the set $Z$ obtained by replacing the word GCC of $Y$ by GTC, is considered, i.e. $Z = \{AAT, ATG, CCT, CTA, GCC, GGC, GTC\}$, then there never exists an ambiguous sequence with $Z$, such as $w$ for $Y$, and then $Z$ is a circular code. The flower automaton is the classical algorithm in code theory to test if a set of words is a circular code or not (without

---

**Table 1:** The common circular code $X$. The common circular code $X$ identified in both eukaryotic and prokaryotic genes: $X_u$, $X_i$, and $X_s$ are the preferential sets of 20 trinucleotides in frames 0, 1 and 2 of genes, respectively.

| $X_u$ | AAC AAT ACC ATC CAG CTC CTG GAC GAG GTC GCT GTA GTC GTT TAC TTC |
| $X_i$ | ACA ATA CCA TCA TTA AGC TCC TGC AAG ACG AGG ATG CCG GTC TAG TCG TGT ACT TCT |
| $X_s$ | CAA TAA CAC CAT TAT GCA CCT GCT AGA CGA GGA TGA CGC CGG TGG AGT CGT TGT CTA CTT |
The trinucleotide set \( \{AAT, ATG, CCT, CTA, GCC, GGC\} \) is not a circular code as the sequence \( w = ATGGCCCTA \) written on a circle can be factorized into words of \( Y \) according to two different ways: ATG, GCC, CTA and AAT, GCC, CCT.

**Figure 4:** A counterexample of a circular code. The set \( Y = \{AAT,ATG,CCT,CTA,GCC,GGC\} \) is not a circular code as the sequence \( w = ATGGCCCTA \) written on a circle can be factorized into words of \( Y \) according to two different ways: ATG, GCC, CTA and AAT, GCC, CCT.

**Method**

**Circular code signal (CCS) method**

We have developed circular code signal (CCS) methods to identify protein coding genes (e.g. [19]), global maximum or minimum of the \( C^i \) code \( X \) in micro RNAs [20], etc. This approach is extended and applied here for the case of frameshift genes. It will reveal periodic signals of circular code \( X \).

Let \( T = \{AAA,\ldots,TTT\} \) be the set of 64 trinucleotides over the 4-nucleotide alphabet \( \mathcal{N} = \{A,C,G,T\} \). Let \( n \in \mathcal{N} \) be a nucleotide, \( t \in T \), a trinucleotide and \( F \), a frameshift gene population with \( N(F) \) sequences \( s \). By convention, the position \( i = 0 \) refers to the frameshift site in a frameshift gene \( s \) and is associated with the nucleotide \( n_i \). In a +1 frameshift gene, \( n_i \) is the bypassed nucleotide and in a −1 frameshift gene, \( n_i \) is the reread nucleotide. By convention, all nucleotides before the frameshift nucleotide (in the 5’ direction) have a negative position \( i < 0 \) and all nucleotides after the frameshift nucleotide (in the 3’ direction), a positive position \( i > 0 \). The sequence \( s \) is considered as a series of nucleotides \( n_j \) and the method reading frame is \( \ldots n_j, n_0, n_1, \ldots \). The sequence \( s \) begins at position \( s_{\text{min}} \) (negative value) and ends at position \( s_{\text{max}} \) (positive value) with a length equal to \( s_{\text{max}} - s_{\text{min}} + 1 \).

All the sequences \( s \) of \( F \) are aligned and centered according to their frameshift site \( i = 0 \). Hence, due to the variations of sequence length, a position \( i \) may not exist with some sequences. Let \( N(i,F) \) be the number of sequences \( s \) of the population \( F \) having a position \( i \). A population \( F \) has a minimum \( i \) position noted \( F_{\text{min}} = \text{Min}_{i \in \mathbb{Z}} \{s_{\text{min}}\} \) (negative value) and a maximum \( i \) position noted \( F_{\text{max}} = \text{Max}_{i \in \mathbb{Z}} \{s_{\text{max}}\} \) (positive value). Obviously, at position \( i = 0 \), the number of sequences is maximal and \( N(0,F) = N(F) \). Let the frame \( i = 0 \) of a sequence \( s \) be the frame established by the trinucleotide \( n_i n_{i+1} n_{i+2} \), and the shifted frames \( 1 \) and \( 2 \) be the frame \( 0 \) shifted by one and two nucleotides in the \( 5’-3’ \) direction, respectively. Thus, the method reading frame is not necessarily the classical codon reading frame.

Let \( w = n_{i-1} \ldots n_{i+3} \) be a window of length 4 \( |w| = 4 \) trinucleotides plus 2 nucleotides added to consider the two shifted frames in this window, where \( n_i \) is the \( i \)th nucleotide in \( s \). Let \( \ell_i \) be the \( \ell \)th trinucleotide, \( i \in \{0,1,2,3\} \) in frame \( \ell \), \( \bar{f} \in \{0,1,2\} \), of \( w \) (Figure 5). Let \( X_f, f \in \{0,1,2\} \), be the three codes \( X_0, X_1 \) and \( X_2 \) in the three frames \( f \).
In a given window \( w \), the function \( \delta_i(t_{i}^{w}) \) indicates whether or not the trinucleotide \( t_{i}^{w} \) belongs to the code \( X_j \)

\[
\delta_i(t_{i}^{w}) = \begin{cases} 
1 & \text{if } t_{i}^{w} \in X_j, \\
0 & \text{otherwise}
\end{cases}
\]  

(1)

Then, the score function \( P(X_j,i,s) \) computes the occurrence of the code \( X_j \) in its associated frame, i.e. \( \# = f \), in a window \( w \) of a sequence \( s \)

\[
P(X_j,i,s) = \frac{1}{N(i,s)} \sum_{w} \delta_i(t_{i}^{w})
\]

The score function \( P(i,s) \) computes the average occurrence of the \( C^\circ \) code \( X \) in a window \( w \) of a sequence \( s \)

\[
P(i,s) = \frac{1}{2} \sum_{j=1}^{2} P(X_j,i,s).
\]

Finally, the score function \( P(i,F) \) computes the occurrence of the \( C^\circ \) code \( X \) in a window \( w \) of \( w \) in frames 0,1 and 2 of \( w \), respectively for all sequences \( s \) having a position \( i \) in \( F \).

\[
P(i,F) = \frac{1}{N(i,F)} \sum_{w} P(i,s).
\]

**Proposition 1:** If in each sequence \( s \) of \( F \) the trinucleotides \( t_{i}^{w} \) of a window \( w \) belong to the set \( X \) such that \( \# = f \) then \( P(i,F) = 1 \) and the intensity of the \( C^\circ \) code \( X \) is maximum.

**Proposition 2:** If in each sequence \( s \) of \( F \) the trinucleotides \( t_{i}^{w} \) of a window \( w \) belong to the set \( X \) such that \( \# \neq f \) then \( P(i,F) = 0 \) and the \( C^\circ \) code \( X \) is absent.

**Proposition 3:** \( 0 \leq P(i,F) \leq 1 \) (consequence of Propositions 1 and 2).

### Circular code periodic signals revealed by the CCS method

The definitions used in this CCS method have properties which allow circular code periodic signals in genes to be identified.

**Property 1:** The indicator function (Formula 1) is based on a set \( X \) of 20 trinucleotides which has the following property: it contains no permuted trinucleotide \( P(w) \) (Definition 7), and thus, in particular, no trinucleotide \( T_{xy} = \{AAA,CCC,GGG,TTT\} \). For example, on the purine/pyrimidine alphabet \( R(Y) \) \( (R=A,G, Y=C,T) \), it was already explained that the class of motifs RRR and YYY have no modulo 3 periodicity in genes (Figure 2 in [21]) as they do not occur in a preferential frame (Table 3(a) in [1]).

**Property 2:** The indicator function (Formula 1) is based on three sets \( X \) associated with the three frames \( f \) in \( \{0,1,2\} \), so that \( X_0 = P(X) \) and \( X_1 = P(X) \), i.e. the frame 1 (2 respectively) is analysed with the trinucleotides of \( X_0 \) permuted by one (two respectively) nucleotides. Note that \( X_0 \) and \( X_1 \) also do not have trinucleotides \( T_{xy} \).

**Property 3:** The window length of 14 nucleotides is in correspondence with the length of the minimal window of 13 nucleotides of the three circular codes \( X_0 \), \( X_1 \) and \( X_2 \) to retrieve the frames 0, 1 and 2 in genes [18]. This sliding window length is very short compared to some classical methods of signal processing for genes ([22] and their subsequent works).

**Property 4:** If a gene population \( F \) has the \( C^\circ \) code \( X \) property (Definition 9) then \( P(i,F) \) has a modulo 3 periodicity.

Indeed, a high score value \( P(i,F) \) in a window \( w \) at position \( i \) followed by two low score values at positions \( i+1 \) and \( i+2 \) reflect a high probability that the reading frame of trinucleotides of \( X \) is in this frame \( i \). From the other side, if the window \( w \) is in the reading frame then the trinucleotides of \( X \) are not identified in frame 0 or frames 2 and 1, respectively. Hence, the score values of windows \( w_{ij} \) and \( w_{i+2j} \) are low. A similar reasoning holds for the codes \( X_0 \) and \( X_1 \) which are permuted trinucleotide circular codes of \( X_0 \) (Definitions 7 and 8).

**Significance level of a modulo 3 periodicity**

A modulo 3 periodicity is quantified by counting the local peaks on a frame according to the following indicator function \( \delta_i(i,F) \)

\[
\delta_i(i,F) = \begin{cases} 
1 & \text{if } P(i+1,F) \leq P(i,F) \leq P(i+1,F) \\
0 & \text{otherwise}
\end{cases}
\]

The significance of this indicator function \( \delta_i(i,F) \) can be evaluated with a binomial test. For a population \( F \) with modulo 3 positions in the range \( [a,b] \), let \( X(F) = \delta_i(i,F) \) be the Bernoulli random variable which is equal to 1 with the probability \( p_0 = 1/3 \) (one chance out of 3 that \( P(i,F) \) at position \( i \) is greater than \( P(i-1,F) \) at position \( i-1 \) and \( P(i+1,F) \) at position \( i+1 \)), and to 0 with the probability \( 1-p_0 = 2/3 \). Its probability law is

\[
\text{Prob}(X(F) = x) = p_0^x(1-p_0)^{1-x} \quad \text{for } x = 0,1.
\]

In the range \([a,b] \) of a population \( F \), the sum of independent variables \( X(F) \) is a Binomial random variable \( Y(F) = \sum_{i=a}^{b} X(F) \) of parameter \( p_0 = 1/3 \) and of order \( n = \lceil (b-a+1)/3 \rceil \), where \( \lceil k \rceil \) is the largest integer not greater than \( k \). Thus, \( n \) is the number of modulo 3 positions in the range \([a,b] \) of \( F \). The variable \( Y(F) \) counts the number \( y \) of modulo 3 maxima among the \( n \) possible values of \( i \) in \([a,b] \). Its probability law is

\[
\text{Prob}(Y(F) = y) = \frac{n!}{y!(n-y)!} p_0^y (1-p_0)^{n-y} \quad \text{for } y = 0,1,...,n.
\]

Figure 5: The structure of the sliding window \( w \) of 14 nucleotides analysing the three shifted frames.
Its expected value is \( E(Y(F)) = np_0 = n/3 \) and its variance, \( V(Y(F)) = np_0(1-p_0) = 2n/9 \).

Let \( p = \frac{y}{n} \) be the observed probability of modulo 3 maxima in the range \([a,b]\) among the \( n = \lceil (b-a+1)/3 \rceil \) possible values. For a population \( F \), the null hypothesis \( H_0: p = p_0 = \frac{1}{3} \) is tested against the alternative hypothesis \( H_1: p > p_0 = \frac{1}{3} \). The hypothesis \( H_0 \) is associated with a random curve in \([a,b]\). The hypothesis \( H_1 \) with \( p = 1 \) is associated with a (perfect) modulo 3 periodicity in \([a,b]\), and with \( \frac{1}{3} < p < 1 \), with an incomplete modulo 3 periodicity in \([a,b]\). Knowing the number \( y \) of maxima in \([a,b]\), the significance level \( \alpha \) of the one-tailed Binomial test is determined as follows

\[
\alpha = \text{Prob}(Y(F) > y) = 1 - \text{Prob}(Y(F) \leq y) = \sum_{i=0}^{\lceil (b-a+1)/3 \rceil} \frac{n!}{i!(n-i)!} p_0^i (1-p_0)^{n-i}. \tag{4}
\]

Note: When \( n \) is sufficiency large and \( p \) is not too close to 0 or 1, i.e. \( n > \text{Max}(5p_0, 5/(1-p_0)) = 15 \), the central limit theorem applies and the approximation of the normal distribution \( Z(F) \) to the binomial distribution \( Y(F) \) can be used as follows

\[
Z(F) = \frac{Y(F) - E(Y(F))}{\sqrt{V(Y(F))}}
\]

and

\[
z = \frac{y - p_0}{\sqrt{p_0(1-p_0)}}.\]

Knowing the number \( y \) of modulo 3 maxima in \([a,b]\), the significance level \( \alpha \) of the one-tailed normal test is determined as follows

\[
\alpha = \text{Prob}(Z(F) > z) = 1 - \text{Prob}(Z(F) \leq z) = 1 - \int_{z}^{\infty} \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}z^2} \, dz.
\]

Exact binomial tests (Formula 3) will be used to evaluate the significance levels \( \alpha \) in Figures 6-10 and in Table 3.

In order to automate the reading frame identification, let \( p(f,a,b,F) \) be the observed probability of modulo 3 maxima in the frame \( f \) of the range \([a,b]\) in the frameshift gene population \( F \). Then, the reading frame \( f, f \in \{0,1,2\} \), in the position interval \([a,b]\) in the frameshift population \( F \) is

\[
\hat{f} = f \text{ such that } p(f,a,b,F) = \text{Max}_{i=0}^{1} \{ p(i,a,b,F) \}.
\]

This statistical approach can be easily extended to evaluate any type of periodicity (modulo 2, modulo 3, etc.).

**Data acquisition**

The frameshift gene populations \( F \) used in this study are extracted from the RECODE 2 database (release 2010; [23, 24, 25]). The RECODE 2 database is a compilation of programmed translational recoding events. It deals with programmed ribosomal frameshifts, codon redefinition and translational bypass occurring in a variety of organisms. Each entry includes the gene, its encoded protein for both normal and alternate decoding, the type of the recoding event involved and the trans-factors and cis-elements that influence recoding.

Our study concerns the \(-1\) and \(+1\) frameshifts of eukaryotic and prokaryotic genes as the common circular code \( X \) has been identified only in these populations and not, for example, in viral genes [1]. Therefore, four gene populations \( F \) are extracted according to the frameshift type and the organism kingdom: \(-1\) frameshifts of eukaryotes EUK\(^{-1}\) and prokaryotes PRO\(^{-1}\), and \(+1\) frameshifts of eukaryotes EUK\(^{+1}\) and prokaryotes PRO\(^{+1}\). Table 2 shows the kingdom, the shift type, the position \( i \) of the range \([f_{\text{min}}, f_{\text{max}}]\) in the frameshift gene populations.

**Results**

Figures 6-9 show the graphical results of the score function \( P(i,F) \) (Formula 2) computed on the four frameshift gene populations \( F \) of eukaryotes and prokaryotes EUK\(^{-1}\), PRO\(^{-1}\), EUK\(^{+1}\) and PRO\(^{+1}\), respectively. The \( x \)-axis represents the position \( i \) of the sliding window in \( F \) and the \( y \)-axis, the score value \( P(i,F) \). For display purposes, the
A modulo 3 periodicity is observed in these four frameshift gene populations. It means that the $C_3$ code $X$ is a main primary structure in these populations. In Figures 6-9, the local peaks are marked according to the frame of their position $i$. The peaks in frame $f = 0$ of the sequence $s$ ($i \mod 3 = 0$) are marked by rhombuses, and those in frames $f = 1$ ($i \mod 3 = 1$) and $f = 2$ ($i \mod 3 = 2$), by squares and triangles, respectively. It must be reported again that the frames here are established according to the frameshift position $i = 0$ and not as usual by the start codon of the sequence $s$, hence $f = 0$ is not necessarily the classical codon reading frame.

The frame that contains most of the local peaks before the frameshift site differs from the one after. Precisely, in Figure 6 of EUK$^{-1}$ and Figure 7 of PRO$^+$, before the frameshift site, the majority of peaks (53% with a significance level $\alpha = 0.565\%$ and 67% with $\alpha = 0.040\%$, respectively) are in frame 0 and after the frameshift site, the majority of peaks (both 62% with $\alpha = 0.018\%$) are in frame 1. In Figure 8 of EUK$^{-1}$ and Figure 9 of PRO$^-$, before the frameshift site, the majority of peaks (94% with $\alpha = 10^{-15}$ and 65% with $\alpha = 0.005\%$, respectively) are in frame 1 and after the frameshift site, the majority of peaks (62% with $\alpha = 0.018\%$ and 88% with $\alpha = 10^{-15}$, respectively) are in frame 0. This change of periodicity frame after the frameshift site is clearly observed in Figures 6-9. In genes without frameshift sites, almost all local peaks are in the
same frame (see for example the pioneer papers at the gene and gene population levels published by [26,27,28] etc.).

Table 3 shows the observed probability \( p(\mathcal{F}, a, b) \) of modulo 3 maxima in the three frames \( \mathcal{F} \) of the ranges \([a,b]\) in the four studied frameshift gene populations \( \mathcal{F} \) before and after their frameshift sites. As expected and in agreement with the figure’s results, in the +1 frameshift genes, the reading frames identified are the frame \( \mathcal{F} = 0 \) before the frameshift site and the frame \( \mathcal{F} = 1 \) after the frameshift site. In the −1 frameshift genes, the reading frames identified are the frame \( \mathcal{F} = 1 \) before the frameshift site and the frame \( \mathcal{F} = 0 \) after the frameshift site. Therefore, the periodicity frame associated to the \( C^0 \) code \( X \) moves in the same direction of translational frameshifting.

This change of periodicity frame is also observed at the individual gene level. For example, Figure 10 shows the computation of \( P(i, \mathcal{F}) \) (Formula 2) on the gene \( abp140 \) which is a +1 frameshift eukaryotic gene identified experimentally [29]. Before the frameshift site, the majority of local peaks (74% with \( \alpha = 10^{-7} \)) are in frame 0 while after the frameshift site, the majority of local peaks (82% with \( \alpha = 10^{-9} \)) are in frame 1. This circular code signal approach by studying the local peaks before and after the frameshift position in individual frameshift genes of the RECODE 2 database identifies successfully the frameshift type (+1 and −1) in 68% of genes.

**Discussion**

Periodic signals of the common circular code \( X \) are identified in the +1 and −1 frameshift genes of both eukaryotes and prokaryotes.
Furthermore, the circular code periodic signal shifts in the same direction of translational frameshifting. This last result confirms a theoretical forecast of circular codes. Indeed, if a circular code is associated with a unique decomposition of a reading frame, a frameshift gene with two successive reading frames should have a shift of this circular code signal.

The statistical results observed suggest two hypotheses concerning the ribosomal translational frameshifting origin. The first hypothesis assumes that the frameshift gene structure is composed of two regions (before and after the frameshift site) which have the same circular code distribution but not in the same frame. When the ribosome scans the mRNA and reaches the second region, then it detects a change in the code distribution and shifts the mRNA forward or backward in order to retrieve the common distribution. The second hypothesis assumes that the circular code distribution is the same in the entire mRNA. A particular motif or secondary structure generates causes the ribosome to shift the reading frame at a certain position. This shift drove frameshift genes to evolve their internal structure by adding or deleting a nucleotide to overcome the shifting side effect.

The common circular code is a structural property associated to genes. The statistical analysis of the RECODE 2 database (release 2010) revealed here that the frameshift genes also have this code property in their primary structure whatever the frameshift type (+1 and -1) and whatever the species kingdom (eukaryotes and prokaryotes).

The properties of this developed CCS method may lead to some considerations in signal processing of DNA sequences in the particular case of genes. Periodicities can be revealed in genes with the following window features: an unexpected short sliding window of 14 nucleotides; a window content based on a subset of trinucleotides, precisely 20 trinucleotides; a subset of 20 trinucleotides with particular properties, precisely no permitted trinucleotides; and a different subset of 20 trinucleotides for each gene frame so that the three subsets are deduced from each other by a number of permutations related to the frame shift, precisely $X_i$ ($X_i$ respectively) in frame 1 (2 respectively) is deduced by one (two respectively) permutation of 20 trinucleotides of $X_i$.

This circular code information may be used directly or combined with existing methods to improve the identification of frameshift genes in genomes and their encoded proteins.
